Abstract

Introduction: When there is a change in the physiological pattern of nasal breathing, mouth breathing may already be present. The diagnosis of mouth breathing is related to nasal patency. One way to access nasal patency is by acoustic rhinometry.

Objective: To systematically review the effectiveness of acoustic rhinometry for the diagnosis of patients with mouth breathing.

Methods: Electronic databases LILACS, MEDLINE via PubMed and Bireme, SciELO, Web of Science, Scopus, PsycInfo, CINAHL, and Science Direct, from August to December 2013, were consulted. 11,439 articles were found: 30 from LILACS, 54 from MEDLINE via Bireme, 5558 from MEDLINE via PubMed, 11 from SciELO, 2056 from Web of Science, 1734 from Scopus, 13 from PsycInfo, 1108 from CINAHL, and 875 from Science Direct. Of these, two articles were selected.

Results: The heterogeneity in the use of equipment and materials for the assessment of respiratory mode in these studies reveals that there is not yet consensus in the assessment and diagnosis of patients with mouth breathing.

Conclusion: According to the articles, acoustic rhinometry has been used for almost twenty years, but controlled studies attesting to the efficacy of measuring the geometry of nasal cavities for complementary diagnosis of respiratory mode are warranted.

Introduction

Nasal breathing plays an important role in vital body functions, such as air filtration, heating and humidification of inspired air, a first defense barrier against inhaled allergens, and protection of the paranasal sinuses, ear cavities and lower airways; as its primary function, nasal breathing prepares the air for its optimal utilization in the lungs. When a person is unable to use his/her nasal airways, changes in physiological nasal breathing pattern will occur and, thereafter, mouth breathing ensues. However, the literature exhibits conflict in defining what is considered normal breathing through the nose, as well as in objectively identifying nasal obstruction. Moreover, although the diagnosis of mouth breathing is related to nasal obstruction, this situation is not always the case, especially when oral breathing mode has become chronic. For decades, specific tests for evaluation of nasal permeability have been used in order to quantify the subjective symptom of nasal obstruction. The Altman graph mirror, for example, is one of the instruments used in clinical practice to assess nasal patency. Its metal plate has a smooth side, and the other side shows millimeter markings, allowing for a precise measurement of the area marked by the nasal exhalation, comparing the condensation area between the nasal cavities. However, acoustic rhinometry is one of the newest methods for statically measuring different segments of the nasal cavity, from the nostrils to the choanae, quickly and non-invasively, and requiring little patient cooperation. The technique is based on the analysis of the nasal cavity’s reflected sound from incident sound waves, taking into account the properties of this sound in relation to the intensity and arrival time of the echo. Therefore, this technique enables the measurement of the distances corresponding to the cross-sectional areas, usually of the nasal valve area and the front and rear areas of the choanae, and the calculation of nasal volumes, allowing the identification of the loci of constrictions that contribute to nasal resistance. This procedure is expected to be the most reliable in cross-sectional and longitudinal studies, and is used for routine, diagnostic, research and surgical purposes. It is a useful aid in following patients who have undergone nasal surgery. Therefore, it is used for both pre-surgical and post-surgical evaluations. The procedure is based on the measurement of the acoustic signal which is reflected back from the nasal cavity, and the time it takes for this signal to return is used to determine the size of the nasal cavity. The equipment used for acoustic rhinometry is relatively simple and easy to use, and the results obtained are highly reliable and reproducible. The technique is also used for the assessment of nasal airflow, and has been shown to be effective in the diagnosis and management of nasal obstruction. The clinical value of acoustic rhinometry rests in its ability to measure nasal geometry, thus being an important tool for the clinical rhinological follow-up, allowing for the discrimination between mucosal functional effects and structural changes related to nasal obstruction, and enabling the quantification of the obstructive symptom at an individual level, and the reporting of changes over time. The test does not provide an etiological diagnosis of nasal obstruction, but it is a reliable tool for the discrimination of the obstructive symptom at an individual level, and the reporting of changes over time. The technique is also used for the assessment of nasal airflow, and has been shown to be effective in the diagnosis and management of nasal obstruction. The clinical value of acoustic rhinometry rests in its ability to measure nasal geometry, thus being an important tool for the clinical rhinological follow-up, allowing for the discrimination between mucosal functional effects and structural changes related to nasal obstruction, and enabling the quantification of the obstructive symptom at an individual level, and the reporting of changes over time. The test does not provide an etiological diagnosis of nasal obstruction, but it is a reliable tool for the discrimination of the obstructive symptom at an individual level, and the reporting of changes over time.
Methods

A systematic literature review was performed from the following databases: LILACS via MEDLINE, MEDLINE via Bireme, MEDLINE via PubMed, SciELO, Web of Science, Scopus, PsycInfo, CINAHL, and Science Direct. The data search occurred from August to December 2013. To this investigation, descriptors and crossings used are shown in Table 1.

The search was conducted by two researchers independently, following criteria of inclusion and exclusion. As inclusion criteria, original articles (whose manuscripts were published in any language) addressing the effectiveness of the instrument of acoustic rhinometry in the evaluation of oral breathing were selected.

Literature review articles and editorials were excluded, as well as those papers with no words referring to the subject discussed in this review, those that did not use the instrument of acoustic rhinometry as a complementary diagnostic, and studies on animals.

The methodological characteristics of articles were addressed according to inclusion criteria, statistical analysis and statistical comparison between selected groups (Table 2).

Results

We can observe in the flow chart the number of items found and selected after applying our inclusion and exclusion criteria, according to descriptors and databases (Fig. 1).

To better present the results and to cover the proposed objectives, it was decided to consider the following variables of the selected articles: author/year, location, type of study, sample, equipment/methods used and results (Table 3).

Discussion

In the twentieth XIX, specifically in 1977, Jackson et al. developed studies on the acoustic reflex technique with the aim to calculate cross-sectional areas of trachea, pharynx and supraglottic region.41 Only in 1989, Hilberg et al.9 introduced the method of rhinometry as an acoustic reflection method, adapted to nasal cavities. Such a method can be defined as an objective assessment of nasal patency (or permeability), based on the reflection of a sound wave and offering information on the dimensions and geometry of nasal cavity.11,12,27,43

The use of this technique in the evaluation of mouth breathers has been maturing over the last twenty years. In this investigation, we found two articles that addressed the proposed theme and perceived heterogeneity between these papers, with respect to the authors and publication periods. In the manuscripts included in our study, the beginning of the use of acoustic reflection technique for breathing-mode evaluation and characterization was observed, following an interval of almost two decades to the applicability of this same technique. From the paper published in 1994 to the year 2013,44,45 no studies depicting the use of acoustic rhinometry as a complementary procedure for the diagnosis of mouth breathing were published.

The objective assessment of nasal permeability in patients with nasal obstruction has been developed with the use of the acoustic reflection method, through investigations in populations with allergic rhinitis, hypertrophy of palatine tonsils and recurrent respiratory infections.\(^1,46-48\) Mouth breathing has been underlined in publications using acoustic rhinometry, as a consequence of nasal obstruction. Due to this fact, we found large gaps between the studies here evaluated.

With respect to the origin, the manuscripts included in this review are from North America (Boston, United States) and South America (Porto Alegre, Brazil).\(^44,45\) However, the last US publication on the proposed issue occurred in 1994, showing that the use of acoustic rhinometry equipment in Brazil continues in its update process in a wide range of populations, including the assessment and diagnosis of oral breathing. In the included manuscripts, we observe similarities regarding the type of study, in which they present specified inclusion criteria, presence of a control group, statistical analysis and statistical comparison between groups. These manuscripts are characterized as quantitative, descriptive analytical study,\(^41\) and as case control study.\(^45\)

The sampling procedure is a relevant aspect underlined in the manuscripts, and revealed a similarity in the small number of subjects in the first article (20; 10 in each group)\(^44\) versus a slightly more than twice (48; 24 in each group) the number of subjects in the second article.\(^45\) It is assumed that the small numbers of individuals presented in these studies may compromise the reproducibility of the findings for the general population. In the manuscripts, the participants’ age is also similar: children between eight and 12 years with an approximate means of 9.1,\(^45\) and 10.1 years.\(^44\) This is in line with other studies using the same technique.

Figure 1  Flow chart: number of articles found.

with pediatric populations, both for mean age and number of participants.\textsuperscript{31,48,49}

In studies evaluating surgical procedures for nasal obstruction, acoustic rhinometry is used to quantify the success of these surgeries. Considering that this is a method available which provides the geometric measure of the nasal cavity by means of a reflected acoustic signal, its result is a wave called rhinogram, which has the typical form of a "W". Thus, this method provides some parameters, such as the minimum cross-sectional area (region of higher resistance to air flow) and volume at specific segments.\textsuperscript{31,49,50}

Another important aspect is how the sample is divided. In both articles included in this review there is a division of two sample groups: a group of mouth breathers and another predominantly with nose breathers. The statistical comparison between groups\textsuperscript{44,45} shows the homogeneity of these variables in our selected studies. This is consistent with studies using the same methodology to compare groups, with predominance of publications studying allergic rhinitis populations and control groups.\textsuperscript{41,48}

In both manuscripts included in this review, the method of acoustic rhinometry to evaluate oral breathing was used. Zavras et al.\textsuperscript{44} used an EK Electronics (Aarhus, Denmark) acoustic rhinometer. This was an observational clinical evaluation of respiratory mode by a pediatric dentist, followed by a questionnaire given to relatives/carers. On the other hand, the Fenterseifer et al.\textsuperscript{45} did not specify which rhinometric equipment was used; on the other hand, these authors performed ENT tests of oroscopy, anterior rhinoscopy and cavum X-ray, in addition to the clinical evaluation of respiratory mode through the Protocol for the Assessment of Children with Learning Disabilities.

Differences in the use of equipment and in materials for breathing mode evaluation between studies were observed, showing that there has not yet been consensus on the assessment and diagnosis of mouth breathers. Moreover, our analysis shows the limited number of publications demonstrating the use of a device that aims to measure the nasal cavity area – a very important resource as a complementary procedure for the diagnosis of patients’ respiratory mode.

The articles in this review were statistically analyzed using the same statistical test for independent samples. In the study published in 1994,\textsuperscript{44} a data analysis was carried out with the paired \textit{t}-test for independent samples; with this test, in the analysis of the total volume of both nostrils, it was found that the values of group B – predominantly with nasal breathers (17.7 ± 4.9 mL) – were significantly higher than those obtained for Group A – with mouth breathers (12.0 ± 4.1 mL). On the other hand, the Spearman correlation test used for the analysis between nasal cavities showed significant correlations between minimum area of each nostril and the corresponding volume of the nostril being analyzed. However, the study published in 2013\textsuperscript{45} reported that in the evaluation of nasal cavity volume by acoustic rhinometry, the results showed no consistent relationship in the comparison between the two groups studied with respect to the sum of the mean volume of nasal cavities (\( p = 0.75 \)). In general, the selected studies show that a decrease in nasal geometry occurs in mouth breathing children. We can infer that the absence of more significant statistic data could be related to the small number of subjects in these studies.

Despite not being directed to oral breathing, a study of 101 subjects demonstrated significant differences in nasal geometry, volume and minimal cross-sectional area between groups with different degrees (mild, moderate and severe) of nasal obstruction.\textsuperscript{57} This finding shows that the study of a greater number of subjects results in better significant differences.

These results indicate the need for more detailed studies in the population of mouth breathers, with investments in objective and quantitative methods, as well as in standardized tests.

Conclusion

In this review, the included studies attest to the use of acoustic rhinometry in the population of mouth breathers. Although there may be a theoretical consensus regarding geometry and volume decreases of nasal cavities in mouth
breathers, it has not yet been possible to demonstrate scientifically and clinically this decrease, compared to nose breathers. According to the articles investigated, this technique has already been applied for almost twenty years, but controlled studies attesting to the efficacy of measuring the area of nasal cavities for complementary diagnosis of respiratory mode are needed.
